# Recap: Direct probabilities and priors

- Both sampling distributions and priors are typically direct probabilities: We must provide contextual information enabling them to be assigned directly, or built from simpler probabilities we can assign directly
- Structural assumptions/ansatzes (e.g., independence, IID) and symmetries often play a key role in determining direct probabilities
- Discrete alternatives + permutation symmetry justifies principle of indifference & uniform prior
- Over continuous spaces the uniform prior can't be universal
- Focused on role of symmetries:
  - lackbox Poisson distribution + scale symmetry o 1/r prior for a rate parameter
  - $\blacktriangleright$  Location family + translation symmetry  $\rightarrow$  uniform prior for location parameter
  - lacktriangle Scale family + scale symmetry  $\to 1/\sigma$  prior for scale parameter
  - On non-compact spaces, such priors are typically improper

# Uninformative PMF from permutation symmetry

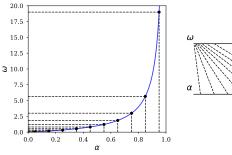

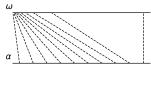

If prior information doesn't distinguish between discrete possibilities, a rule that is consistent across problem formulations will have relabeling symmetry  $\rightarrow$  assign equal probabilities

#### Uniform PDF can't be universal

Consider two parameterizations of a binomial sampling dist'n:

- Success probability,  $\alpha$ :  $p(n|\alpha) \propto \alpha^n (1-\alpha)^{N-1}$
- Odds,  $\omega \equiv \alpha/(1-\alpha)$ :  $p(n|\alpha) \propto \left(\frac{\omega}{1+\omega}\right)^n \left(\frac{1}{1+\omega}\right)^{N-1}$

Uniform over  $\alpha$  is inconsistent with uniform over  $\omega$ !

Is there a "natural" way to pick intervals we should consider equally probable a priori?

### Priors derived from the likelihood function

Few common problems beyond location/scale problems admit a transformation group argument  $\rightarrow$  we need a more general approach to formal assignment of priors that express "ignorance" in some sense

There is no universal consensus on how to do this (yet? ever?)

A common underlying idea: The same  $\mathcal C$  appears in the prior,  $p(\theta|\mathcal C)$ , and the likelihood,  $p(D|\theta,\mathcal C)$ —the prior "knows" about the likelihood function, although it doesn't know what data values will be plugged into it (e.g., the symmetry eqns  $\leftarrow$  likelihood)

**Jeffreys priors**: Uses Fisher information to define a (parameter-dependent) scale defining a prior; parameterization invariant, but strange behavior in many dimensions

**Reference priors**: Uses information theory to define a prior that (asymptotically) has the least effect on the posterior; complicated algorithm; gives good frequentist behavior to Bayesian inferences

# Jeffreys priors: Heuristic motivation

- Dimensionally,  $\pi(\theta) \propto 1/(\theta$  scale) e.g., uniform prior  $= 1/\Delta \theta$
- Use the likelihood function to determine a (relative) scale at each  $\theta$ , say,  $s(\theta)$ , and then set  $\pi(\theta) \propto 1/s(\theta)$
- Seek a scale definition that produces priors that are consistent WRT reparameterization (this was Harold Jeffreys' main desideratum)

Such a prior essentially specifies a way to slice-and-dice the  $\theta$  axis so assigning equal probability to intervals reflects inherent scales, and is consistent WRT reparameterization

## **Jeffreys priors: Implementation**

• If we have data D, a natural scale at  $\theta$ , from the likelihood function, is the **inverse square root** of the *observed Fisher information* (recall Laplace approximation, where this gives  $1/\sigma^2$  at  $\hat{\theta}$ ):

$$I_D(\theta) \equiv -\frac{\mathrm{d}^2 \log \mathcal{L}_D(\theta)}{\mathrm{d}\theta^2}$$

• For a prior, we don't know D; for each  $\theta$ , average over D predicted by the sampling distribution; this defines the (expected) Fisher information:

$$I(\theta) \equiv -\mathbb{E}_{D|\theta} \left[ \frac{\mathrm{d}^2 \log \mathcal{L}_D(\theta)}{\mathrm{d}\theta^2} \right]$$

• Invariance: Can show for  $\phi = \Phi(\theta)$ , and  $\theta = \Theta(\phi)$ :

$$I(\phi) = I(\theta) \left(\frac{\mathrm{d}\Theta}{\mathrm{d}\phi}\right)^2$$

## Jeffreys' prior

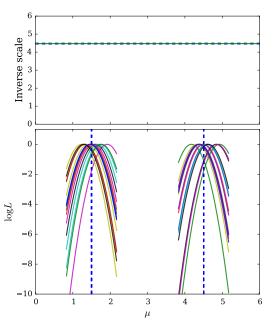

$$\pi(\theta) \propto [I(\theta)]^{1/2}$$

- Puts more weight in regions of parameter space where the data are expected to be more informative—roughly speaking, says the choice of experiment reflects expectations of what value  $\theta$  may take
- Automatically consistent w.r.t. reparameterization ("invariant"):

$$\sqrt{I(\phi)} = \sqrt{I(\theta)} \left| \frac{\mathrm{d}\Theta}{\mathrm{d}\phi} \right| \quad o \quad \pi(\phi) = \pi(\Theta(\phi)) \left| \frac{\mathrm{d}\Theta}{\mathrm{d}\phi} \right|$$

- Typically improper when parameter space is non-compact
- Improves frequentist performance of posterior intervals w.r.t. intervals based on flat priors
- Only considered sound for a single parameter (or considering a single parameter at a time in some multiparameter problems)

#### Jeffreys prior for normal mean

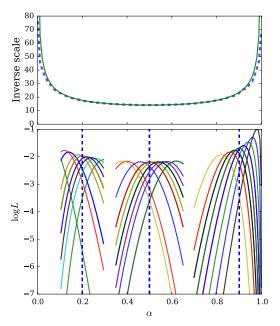

N=20 samples from normals with  $\sigma=1$ 

Likelihood width is independent of  $\mu \Rightarrow$ 

$$\pi(\mu) = \mathsf{Const}$$

Another justification of the uniform prior Prior is improper without prior limits on the range

## Jeffreys prior for binomial probability

Binomial success counts n from N = 50 trials

$$\pi(\mu) = \frac{1}{\pi \alpha^{1/2} (1 - \alpha)^{1/2}}$$
$$= \text{Beta}(1/2, 1/2)$$

## Limitations of the Jeffreys prior

- Only considered sound for a single parameter (or considering a single parameter at a time in some multiparameter problems) E.g., for  $\mathrm{Norm}(\mu,\sigma)$ , the Jeffreys prior is  $\propto 1/\sigma^2$ , not the product of separate Jeffreys  $\mu$ ,  $\sigma$  priors
- Only applicable to continuous spaces
- $\rightarrow$  Seek more formal notions of "objective" or "uninformative" that reproduce good things about the Jeffreys prior

Reference priors largely accomplish this, using ideas from information theory

Supplementary material on reference priors. . .

# Uncertainty, information, and entropy

Other rules for assigning "non-informative" priors rely on a more formal measure of the *information content* (or its complement, amount of *uncertainty*) in a probability distribution

Intuitively appealing metric-based measures, like standard deviation or interval size, are not general enough; e.g., they don't apply to categorical distributions

Desiderata for an uncertainty functional  $S_N[\vec{p}]$ —a map from a PMF  $\vec{p}=(p_1,p_2,\ldots,p_N)$  to a single scalar quantifying the amount of uncertainty it expresses (treat PDFs later):

- $S_N[\vec{p}]$  should be continuous w.r.t. the  $p_i$ s
- Uncertainty grows with multiplicity: When the  $p_i$  are all equal,  $s(N) = S_N[\vec{p}]$  should grow monotonically with N
- Additivity over subgroups
- $\Rightarrow$  functional equations for  $S_N[\vec{p}]$

# Information Gain as Entropy Change

#### Entropy and uncertainty

Shannon entropy = a scalar measure of the degree of uncertainty expressed by a probability distribution

$$S = \sum_{i} p_{i} \log \frac{1}{p_{i}}$$
 "Average surprisal"  
$$= -\sum_{i} p_{i} \log p_{i}$$

#### Information gain

Information gain upon learning D = decrease in uncertainty:

$$\mathcal{I}(D) = \mathcal{S}[\{p(H_i)\}] - \mathcal{S}[\{p(H_i|D)\}]$$

$$= \sum_{i} p(H_i|D) \log p(H_i|D) - \sum_{i} p(H_i) \log p(H_i)$$

## A 'Bit' About Entropy

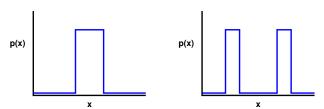

#### Entropy of a Gaussian

$$p(x) \propto e^{-(x-\mu)^2/2\sigma^2} \qquad \rightarrow \quad \mathcal{S} \propto \log(\sigma)$$

$$p(\vec{x}) \propto \exp\left[-\frac{1}{2}\vec{x}\cdot\mathsf{V}^{-1}\cdot\vec{x}\right] \ o \ \mathcal{S} \propto \log(\det\mathsf{V})$$

→ Asymptotically like log Fisher matrix

A log-measure of "volume" or "spread," not range

These distributions have the same entropy/amount of information.

#### Expected information gain

When the data are yet to be considered, the *expected* information gain averages over D; straightforward use of the product rule/Bayes's theorem gives:

$$\mathbb{E}\mathcal{I} = \int dD \, p(D) \, \mathcal{I}(D)$$

$$= \int dD \, p(D) \, \sum_{i} p(H_{i}|D) \log \left[ \frac{p(H_{i}|D)}{p(H_{i})} \right]$$

For a continuous hypothesis space labeled by parameter(s)  $\theta$ ,

$$\mathbb{E}\mathcal{I} = \int dD \, p(D) \, \int d heta p( heta|D) \log \left[rac{p( heta|D)}{p( heta)}
ight]$$

This is the expectation value of the *Kullback-Leibler divergence* between the prior and posterior:

$$\mathcal{D} \equiv \int d heta \, p( heta|D) \log \left[rac{p( heta|D)}{p( heta)}
ight]$$

## Reference priors

Bernardo (later joined by Berger & Sun) advocates *reference priors*, priors chosen to maximize the KLD between prior and posterior, as an "objective" expression of the idea of a "non-informative" prior: reference priors let the data most strongly dominate the prior (on average)

- Rigorous definition invokes asymptotics and delicate handling of non-compact parameter spaces to make sure posteriors are proper
- For 1-D problems, the reference prior is the Jeffreys prior
- In higher dimensions, the reference prior is not the Jeffreys prior; it behaves better
- The construction in higher dimensions is complicated and depends on separating interesting vs. nuisance parameters (but see Berger, Bernardo & Sun 2015, "Overall objective priors")
- Reference priors are typically improper on non-compact spaces
- They give Bayesian inferences good frequentist properties
- A constructive numerical algorithm exists
